EXECUTIVE SUMMARY

The Town of Patagonia (Town) and Arizona Minerals Inc. (AMI) retained Clear Creek Associates as a third-party consultant to conduct an evaluation of the potential discharge of 10 cubic feet per second or cfs (4,500 gallons per minute or gpm) of treated water from the AMI Hermosa Project into Harshaw Creek. The Town of Patagonia was concerned that the additional flow to Harshaw Creek would negatively increase groundwater levels through recharge along Harshaw and Sonoita Creeks as well as exacerbate flood flows in the Town. Clear Creek Associates met six (6) times with the Town and AMI personnel to confirm the scope of work, review the progress of the work, exchange information pertinent to the modeling, and discuss the model results at various stages of development. The modeling performed as part of the project was designed to quantify impacts using industry-accepted techniques, assumptions, and software.

The result of the modeling indicates that a constant inflow of 10 cfs to Harshaw Creek from WTP2 would have minimal impacts to flood flows in the Town during the simulated 2-year, 10-year, and 50-year, 24-hour storm events. Projected surface water level (stream stage) rises attributable to the 10 cfs are less than one inch for all storm events. As indicated in **Table 4**, 10 cfs is a very small percentage of even the 2-year storm event, therefore, the impact to stormwater stage height is small.

The groundwater modeling shows that the addition of 10 cfs to Harshaw Creek would cause groundwater mounding along both Harshaw and Sonoita Creeks, with the maximum predicted groundwater mounding to be about 4.5 feet after 5 years of flow. The area of projected maximum water level rise is where Harshaw Creek enters the basin. Within the Town, projected water level rises are mostly in the range of 2 to 3 feet. After five years of recovery, groundwater levels were predicted to return to pre-discharge levels. Additional groundwater mounding from flood events on top of the long-term discharge impacts was also evaluated. For the largest flood event, the 50-year, 24-hour event, additional mounding of up to two feet may occur. No simulations indicated groundwater rising to ground surface except in the areas of predicted perennial flow along Sonoita Creek where groundwater levels are already at the ground surface.

1.0 INTRODUCTION

Clear Creek Associates, LLC ("Clear Creek") was retained by Arizona Minerals, Inc. ("AMI") and the Town of Patagonia ("Town") to provide a third-party evaluation of possible impacts from planned water treatment plant discharges to Harshaw Creek. AMI, a Nevada corporation doing business in Arizona, is an independent company whose ultimate parent is South32, a mining company organized under Australian law. AMI is developing the Hermosa Project, a future underground mine in the Patagonia Mountains south of the Town. The purpose of this evaluation was to assess whether the discharges from mine dewatering operations would increase potential flooding impacts in and around the Town.

AMI is in the process of obtaining permits to discharge treated water from a second proposed water treatment plant (WTP2) to Harshaw Creek as part of the Hermosa Project. Harshaw Creek flows into Sonoita Creek just upstream of the Town (**Figure 1**). The discharge to Harshaw Creek from WTP2 of up to 4,500 gallons per minute or gpm (or 10 cubic feet per second or cfs) will occur 10 miles upstream of the Town. The exact duration of flow from WTP2 is uncertain at this time, and may continue for several years while underground facilities are constructed. The Town is concerned with the potential impact on both Harshaw Creek and Sonoita Creek in terms of groundwater mounding and surface water level (stage) rise in the creeks during storm events.

Clear Creek has developed a surface water model to evaluate impacts of the additional flow from WTP2 on stage in portions of Harshaw Creek and Sonoita Creek during storm events. A separate groundwater model was developed to evaluate groundwater mounding during the continuous flows, as well as the impact of the additional flow in the creek during storm events. Development and results of the surface water model is described in Sections 5 and 7, and the groundwater model development and results are described in Sections 6 and 8.

WTP2 will treat water from the following sources:

- Groundwater pumped from a wellfield to depressurize and dewater the fractured rock aquifer.
- Groundwater and operational water pumped from underground workings
- Treated water from water treatment plant number one (WTP1)
- Drilling water and core cutting water
- Water from stormwater Best Management Practices

WTP2 will be constructed to treat up to 10 cfs. The water discharged from the plant will meet all applicable surface water and groundwater quality standards. WTP2 will be constructed near Harshaw Creek at the site shown on **Figure 1**, 10 miles upstream of the location where Harshaw Creek flows into Sonoita Creek. The confluence of Harshaw Creek and Sonoita Creek is approximately a third of a mile upstream of the point where Sonoita Creek crosses Highway 82, on the northeast edge of the Town's main business center.

2.0 DATA SOURCES

The evaluation relied on existing data available from published reports and maps, publicly accessible databases, and information provided by AMI, the Town and interested citizens. In accordance with the approved Scope of Work, Clear Creek did not attempt to generate any new data for this project, with the exception of a field visit conducted on February 26, 2021, to verify locations of wells and inspect the conditions along major stream channels.

For the groundwater model, we obtained the following data. The use of these data is described in Section 6.

Data Type	**Sources**
Geology, aquifer composition and depth	• Geologic map by the United States Geological Survey (USGS; Drewes, 1996) • Surface geophysical survey for the Town of Patagonia (Clear Creek, 2016) • Well driller logs from Arizona Department of Water Resources (ADWR) Wells 55 Imaged Records database • Statewide depth to bedrock contours from the Arizona Geological Survey (AGS; Richard et al., 2007) • University of Arizona thesis on the hydrogeology of the Sonoita basin (Nassereddin, 1967)
Aquifer hydraulic conductivity	• University of Arizona thesis on the hydrogeology of the Sonoita basin (Nassereddin, 1967)
Aquifer storativity	• University of Arizona thesis on the hydrogeology of the Sonoita basin (Nassereddin, 1967)
Groundwater inflows and outflows along Sonoita Creek	• University of Arizona thesis by Robotham (1979)

Precipitation and groundwater recharge	• Climate data from the PRISM Climate Group at Oregon State University
Groundwater pumping	• Town of Patagonia • ADWR Wells-55 registry, 2021
Streamflow rates	• The Nature Conservancy and USGS stream gage data
Groundwater levels	• ADWR Groundwater Site Inventory (GWSI) database • ADWR Well 55 Database, 2021

A digital elevation model (DEM) was used for determining watershed topographic characteristics in the hydrologic model and for extracting cross section elevation data for the hydraulic model. DEMs are gridded surfaces of point elevations used to represent topography.

2.1 Hydrologic Model DEM

For the hydrologic model, a 4-foot resolution DEM from LiDAR was obtained from the Santa Cruz County website. This DEM covers the entire watersheds of Sonoita Creek (upstream of Harshaw Confluence), Red Rock Creek, and Harshaw Creek so that hydrologic parameters for these watersheds can be determined. For the purposes of watershed characterization, a 4-foot resolution was sufficient and expedited the processing time.

2.2 Hydraulic Model DEM

The DEM used for the hydraulic model focused on the area around the Town. Because this DEM is used to help define cross sections and understand channel geometry, it's important to use the highest resolution data available. Two datasets were used to generate the DEM for the hydraulic model:

- 1-foot contours for the Town and its immediate vicinity which was obtained from the Town;

- 2-foot and 4-foot contours obtained from Santa Cruz County were used to supplement the extent of the 1-foot contour data where it did not fully cover the floodplain.

2.3 Field Observations

After the process of constructing hydrologic and hydraulic models had begun, Clear Creek made a trip to the site on February 25, 2021, along with members of the Town to gather data and photograph key areas for the hydraulic model (e.g. bridges, boundaries, etc.). The observations made during this trip verified assumptions that were made when constructing the surface water models.

3.0 STUDY AREA DESCRIPTION

3.1 Conceptual Hydrogeologic Model

Using the data described in Section 2.1, a conceptual hydrogeologic model of the Study Area was developed. Key elements of the conceptual hydrogeologic model are summarized below, followed by a discussion of the Study Area's surface water hydrology.

3.1.1 Regional Geology

The Sonoita Area is characterized by an alluvial fill valley, surrounded by a wide variety of sedimentary and volcanic rocks. **Figure 2** illustrates the regional geology in the area of the site, and the alluvium is shown as the QTg unit. The groundwater flow model area and no-flow (non-calculation) cells are also shown for reference. The underlying bedrock units are significantly less permeable than the alluvium, but are likely to transmit some groundwater.

3.1.2 Aquifer Extent and Thickness

The Study Area is oriented north-northeast to south-southwest and extends approximately 10 miles from a bedrock constriction located downstream of the Town of Sonoita to a bedrock constriction located downstream of the Town (**Figure 2**). The focus of the study is the alluvial groundwater basin surrounding Sonoita Creek. The basin consists of Tertiary to Quaternary-aged basin-fill alluvium surrounded and underlain by older, less permeable bedrock. Within the Study Area, alluvium is exposed at the land surface over an area of approximately 35 square miles. Based on available data from water well drillers' logs and statewide depth-to-bedrock contours, the alluvium appears to be more than 450 feet thick near the middle of the Study Area. Near the Town, a geophysical survey indicated the thickness of the alluvium is at least 300 feet (Clear Creek, 2016). Along the edges of the basin, the alluvium is most likely a thin veneer overlying the bedrock and is unlikely to be saturated.

3.1.3 Water Balance

The focus of the Study Area is the shallow basin fill aquifer system in Sonoita Valley that would be most directly impacted by shallow surface water flows along Harshaw and Sonoita Creeks. For this reason, the water balance appropriate for this study must be derived for the inflow and outflow components of the shallow groundwater system. The underlying bedrock, although it contains groundwater, would not significantly contribute flow to the shallow aquifer system. Downstream of the Town, Sonoita Valley narrows and bedrock comes to the ground surface. This causes shallow groundwater moving down Sonoita Valley to be forced to the ground surface as surface water creating the observed perennial flow in Sonoita Creek. Therefore, to derive a water balance for the shallow aquifer, it is appropriate to rely on the observed surface water flow in Sonoita Creek to estimate the inflows and outflows of the shallow aquifer system.

The water balance for the Study Area (**Table 1**) includes all water that is added to the shallow aquifer and all water that leaves the shallow aquifer. There are four primary sources of water to the aquifer: runoff from precipitation and snowmelt in the surrounding mountains, mountain front and mountain block recharge, underflow from areas upstream of the Study Area along Sonoita Creek, and recharge of treated effluent from the Town's wastewater treatment plant.

Water leaves the aquifer as streamflow along Sonoita Creek, bedrock underflow along Sonoita Creek downstream from the Town, and groundwater pumpage. Additional water leaves the aquifer via evapotranspiration, primarily from stands of riparian vegetation in and south of the Town. Locations of inflows and outflows are shown on **Figure 3**.

Outflows

The largest outflow from the Study Area is Sonoita Creek base flow. This volume is roughly 3,300 AF/yr (4.6 cfs), based on stream gage data from the Nature Conservancy for the years 1992-2020. Underflow is a minor component of outflow only occurring in the immediate vicinity of the Sonoita Creek channel. Using assumptions regarding

permeability, hydraulic gradient, and width of the underflow zone[1], the estimated underflow in bedrock is about 146 AF/yr (0.2 cfs). Evapotranspiration (ET) was estimated using data from CropScape. The process of estimating ET involved using the crop survey data from the CropScape website (https://nassgeodata.gmu.edu/CropScape/) which is maintained by the National Agricultural Statistical Service (NASS). CropScape is a web-search program to interact with the NASS Cropland Data Layer, which is an annual raster image with pixels coded by crop type. CropScape includes categories of vegetation listed as "Woody Wetlands" and "Herbaceous Wetlands". This acreage corresponds closely with phreatophyte vegetation along the Sonoita Creek, taking water directly from shallow groundwater. The CropScape data yielded an ET of 94.5 AF/yr (0.13 cfs).

Groundwater pumpage is relatively minor in the Study Area. The Study Area is outside any of Arizona's designated Active Management Areas, where groundwater pumpage is regulated by ADWR, so private well owners are not required to report their pumpage. However, pumpage data were available from the Town. Also, it is possible to roughly estimate non-Town pumpage based on the number of registered wells in the Study Area and an assumption of 0.5 AF/yr per well, which is consistent with guidance that ADWR has provided on past groundwater modeling projects conducted in Arizona (Obenshain, 2018). The well database compiled for the Study Area includes 1,171 wells, with 417 wells in the active model area. After reviewing the well records, 317 wells were selected as wells with presumed water use, as illustrated in **Figure 4**. Of these wells, 315 are small domestic users, with total pumpage estimated at 157.5 AF/yr (0.22 cfs). The Town has two wells, and these wells were simulated using their average pumping rates. Pumpage from the Town wells averages 55.6 and 53.7 AF/yr (0.08 and 0.07 cfs). This equates to a total pumping rate of roughly 270 AF/yr (0.37 cfs) for the Study Area. This is a relatively small volume compared to the other components of the water budget.

[1] Underflow mainly occurs in a zone about 700 feet wide spanning Sonoita Creek through the upper 500 feet of bedrock yielding an area of 350,000 square feet. The hydraulic gradient is about 0.01 ft/ft and, at an assumed average hydraulic conductivity of 5 ft/day this yields an underflow of 146 AF/yr.

Inflows

As discussed above, a key feature of the Study Area is that groundwater is forced to the ground surface downstream of the Town due to shallow bedrock and a narrowing of the valley. Therefore, in this case, it is possible to use the measurements of surface flow and assumptions on ET, well pumping, and underflow to estimate the inflow to the Study Area. As shown on **Table 1**, the total inflow from recharge to the basin and underflow along Sonoita Creek above the Study Area must equal the outflow calculated for the basin minus the inflow from effluent discharge from the Patagonia wastewater treatment plant. Inflow from recharge and underflow then equals 3,691 AF/yr (5.1 cfs) with an additional contribution from the effluent discharge of 100 AF/yr (0.14 cfs).

3.1.4 Groundwater Levels, Trends, and Flow Direction

Groundwater flows into the Study Area from the highlands to the west (the Santa Rita Mountains), the east (the Patagonia Mountains), and from the north from the upper reaches of Sonoita Creek. The flow generally parallels Sonoita Creek. In the northern portion of the model the hydraulic gradient is approximately 0.013 feet/feet along Sonoita Creek and in the area of the Town, it decreases to approximately 0.006 feet/feet.

Clear Creek compiled water level data from a variety of sources, including ADWR Ground Water Site Inventory (GWSI) and registered well (Wells 55) databases for the Study Area. **Appendix A** includes a listing of available groundwater level data, which spans the period from 1908 to 2021, including 743 measurements for the area withing one-mile of the model domain. The Study Area is generally considered to be in a long-term steady-state condition, as no non-natural stresses large enough to affect regional groundwater levels have been added. For this reason, average groundwater levels were calculated from the available data, and are presented in **Figure 5**. Groundwater flow in the area is illustrated by the water level contours, which indicate that flow is generally parallel to Sonoita Creek. Groundwater level data were available at 65 points in the Study Area.

Depths to water vary considerably because of the topography of the land surface. **Figure 6** shows the average depth to water for the model area. In the Town, the water

level elevation in the Town's wells is approximately 40 feet below land surface, and **Figure 7** shows the minimum depth to water measured at each well. The shallowest measured groundwater level is 7 feet, at a well located beyond the western limit of the Town, near Sonoita Creek. Groundwater levels are generally shallower near Sonoita Creek and deeper toward the east and west boundaries of the Study Area.

4.0 GENERAL PROJECT APPROACH

The evaluation of potential flooding impacts was conducted in close coordination with AMI and the Town. The evaluation consisted of groundwater modeling to estimate groundwater mounding in the Sonoita Creek Basin near the Town resulting from infiltration of the proposed 10 cfs flow from the WTP2 discharge, and surface water modeling to estimate the flooding impacts from additional water in the Harshaw and Sonoita Creek channels. An overview of the groundwater and surface water modeling approach is provided below. More detailed descriptions of the models are provided in Sections 6 and 7.

4.1 Groundwater Model

The numerical groundwater flow model used the United States Geological Survey (USGS) model code MODFLOW-NWT and the graphical user interface Groundwater Vistas™ by Environmental Simulations, Inc. All model input and output files used Groundwater Vistas (v. 8.07 build 1) and ESRI's ArcGIS software (v. 10.7.0.10450).

MODFLOW simulates the behavior of groundwater in three dimensions. It divides an aquifer into cells organized into rows, columns, and layers (**Figure 8**), with each model cell assigned the aquifer properties of hydraulic conductivity and storage. Other model inputs include recharge to the aquifer, underflow from outside the model domain, groundwater pumpage, and evapotranspiration. The MODFLOW Stream Flow Routing (SFR) Package simulates the interaction between groundwater and surface water along a stream. Model outputs include predicted groundwater elevations and the locations and rates of groundwater discharge to the surface (e.g., base flows in streams).

4.2 Surface Water Model

The primary purpose for constructing a surface water model in this study is to evaluate the incremental risk of flooding within the Town due to a maximum of 10 cfs continuous discharge into Harshaw Creek. Note that no losses of discharged flow are assumed to occur along Harshaw Creek until the flow reaches Sonoita Valley. While detailed flood

studies (FEMA 2011) have been conducted for the area by the United States Department of Homeland Security's Federal Emergency Management Agency (FEMA), these studies did not include the maximum 10 cfs discharge from the Harshaw Creek from WTP2.

The surface water model consists of two parts, a hydrologic model and a hydraulic model. The hydrologic model determines how water runs off of contributing watersheds during storm events, and the hydraulic model analyzes how water moves through the creeks and floodplain.

4.3 Model Simulations

The groundwater and surface water models were used together to evaluate the potential impacts on flooding along Sonoita Creek and Harshaw Creek near the Town. The groundwater model was first calibrated to historical (steady state) conditions that existed prior to 2007, then calibrated to transient conditions from 2007 through 2020. Model calibration consisted of matching the output (simulated groundwater levels and base flows along Sonoita Creek) to measured data. Various model inputs, including recharge rates and aquifer hydraulic conductivity, were adjusted as needed until the model adequately replicated the measured data. Model calibration is discussed in more detail in Section 6.2.

After the groundwater model was calibrated, recharge of 10 cfs from WTP2 was simulated to evaluate whether the recharge of this water would cause groundwater levels to rise high enough to saturate the land surface and/or increase the base streamflow rate along Sonoita Creek near the Town.

The surface water model predictions with the additional 10 cfs of flow were applied to the groundwater flow model to evaluate the potential impacts on flooding and groundwater level rise. As no increase in baseflow within the surface water model study area was observed in the groundwater model, flows due to rising groundwater were not included in the surface water model. Any changes in infiltration rate due to saturation of the stream bottom are sufficiently accounted for in the surface water model's conservative assumption that no infiltration will occur.

The predictive simulations are described in more detail in Section 8.

5.0 HYDROLOGY

5.1 Climate

The climate in the Study Area varies from high desert in the Sonoita Valley to the steppe-like climate of the higher elevation grasslands and scrub area (ADEQ, 2003). Average rainfall in the Harshaw Creek subwatershed is 19.95 inches per year (Oregon State University PRISM Climate Group, 2021), with the majority of precipitation occurring between June and October through convective thunderstorms. Measured annual and monthly precipitation for July 1921 through October 2017 is presented in **Appendix B** (NCDC, 2021). There is occasional snowfall at higher elevations during the winter months that usually melts within a few days. The highest annual precipitation was 27.9 inches in 1992, and the highest monthly total was 9.60 inches in July 1950.

5.2 Surface Water Hydrology

The Study Area is located within the Sonoita Creek and Harshaw Creek watersheds, and their tributaries (**Figure 9**). Harshaw Creek joins Sonoita Creek just upstream from the Town, along with a significant tributary, Redrock Canyon. Sonoita Creek flows to the west as a tributary of the Santa Cruz River. Sonoita Creek is mapped as perennial from just downstream of the Town as noted in **Figure 9**. As noted, all other streams in the Study Area are ephemeral or intermittent.

Figure 9 also illustrates the domain selected for the development of the numerical groundwater flow model, which encompasses the Harshaw Creek and Middle and Upper Sonoita Creek watersheds.

5.3 Springs

Figure 9 illustrates the identified springs and seeps in the model domain, based on review of USGS, USFS and site investigations conducted for this project. No springs are located within the model domain.

5.4 Wells and Water Levels

In order to assess the regional groundwater conditions, an evaluation of available well records was undertaken to properly locate wells in the area. This assessment began by selecting registered well records from the Wells 55 Registry Database (ADWR, 2021) in the area of interest. The selected well records were copied into a shapefile which forms the well database for the project, which is shown on **Figure 10**. The projection of the shapefile was adjusted to conform to Arizona State Plane, Central Zone, NAD 83. The numerical groundwater model used this same projection with coordinates in feet.

Fields were added to the database to accommodate:

- Perforation or screened interval – critical for loading water level or pumping data from the wells into the model;
- Well name – local name for well or core hole;
- Well Elevation – to determine water level elevations if depth to water is reported; and,
- Azimuth and Inclination for the angled core holes.

The well database serves as the cornerstone for hydrologic data collected, particularly water levels. Since all wells are not registered with ADWR, unregistered wells added to the database are assigned numbers starting with 1001. These are generally wells with water levels in the GWSI database which do not appear to be registered. The well registry number is the key field for the database, with water level data linked to the well registry number.

Appendix C is a database of information for 1,171 wells, covering the Study Area and the Hermosa Project site both inside and outside the model domain. **Figure 10** illustrates well locations in the well database. It should be noted that the elevations and well screen information were updated for wells with water level or pumping data.

5.5 Water Level Data

Water level data are available from the ADWR GWSI database (ADWR, 2021b) for areas across the state, although these data are generally very limited in both areal coverage

and historical entries. **Figure 5** illustrates the available wells color coded with the number of groundwater level measurements available for each well in the database. A significant effort was undertaken to assess individual wells to see if additional groundwater level data could be identified to form a basis for the model development. Many wells have reported depth to water associated with their well registration records, but lack the top of well elevation information. Because wells are only reported using the closest 10-acre legal description, they are not generally reported with precise enough locations to determine the well elevation adequately. Using parcel information and other data in ADWR well registry records, it was possible to more accurately locate additional wells using Google Earth imagery. This also provided surface elevations for wells found on Google Earth. This allowed for additional groundwater level elevations to be added to the database.

5.5.1 Well Pumping Records

Because the model domain is not within the boundaries of an ADWR Active Management Area (AMA), groundwater pumping is not generally required to be reported. However, reporting of pumping for water providers has been required by ADWR since 2006. **Table 2** lists the reported pumping (acre-feet per year) for the model domain:

Table 2 – Pumping Reported to ADWR

Owner	Well Number	Total	2006	2007	2008	2009	2010	2011	2012	2013
Red Rock Acres HOA	807106	26.23	3.00	3.00	2.56	3.00	2.53	2.79	3.18	3.51
Town of Patagonia	605596	581.60	82.00	64.00	60.40		70.70	56.70	70.40	73.00
Town of Patagonia	605595	570.21	58.00	64.00	56.91		54.90	71.30	59.60	70.00
			2014	**2015**	**2016**	**2017**	**2018**	**2019**	**2020**	
Red Rock Acres HOA	807106	26.23	2.66							
Town of Patagonia	605596	581.60	68.00	36.40	53.66	62.91	56.72	51.74	52.59	
Town of Patagonia	605595	570.21	59.00	76.50	55.55	53.52	49.72	43.08	55.07	
Note: Data in AF/yr										
	2018 data missing month of August									
	2019 data missing month of March									

The locations of these wells are shown on **Figure 4**.

5.5.2 Agricultural Water Use

Groundwater pumping can be used for agricultural irrigation. Since surface water diversions for agricultural irrigation are not known in the area, it is assumed that any agricultural activity is supported through groundwater pumping. The National Agricultural Statistics Service (NASS) maintains an aerial photographic archive for the U.S. which classifies each pixel by crop type, using infrared/visible light band responses (the Cropland Data Layer – CDL). The NASS CropScape data is also described above in Section 3.1.3. These coded raster images are available for Arizona from 2008 to 2020, with each pixel of the image representing 0.22 acres. The NASS does conduct a limited number of verification surveys to determine whether the crop type assessments are accurate, but the sensor band response is the principal source of data. The data also include non-agricultural plant communities, such as shrubland, evergreen forest and woody wetlands. **Figure 11** illustrates CropScape CDL image for 2020 for the model area. Much of the area is dominated by shrubland and evergreen forest. **Figure 12** shows the plant types for 2020 near the Town which would represent irrigated crop

lands. Only 42 pixels were noted for potential irrigated crops, which would be 9.24 acres. Based on these values, it appears that potential agricultural irrigation is minimal in the model area, likely never exceeding 40 AF/y. For this reason, agricultural irrigation was not included as pumping from the model.

5.5.3 Phreatophytes and Evapotranspiration

As mentioned in Section 3.1.3, the other significant value of the CropScape CDL dataset is the mapping of Woody Wetlands and Herbaceous Wetland categories. These categories map phreatophyte communities, which allows for estimating phreatophyte distribution. Using the CDL data, model cells were selected where phreatophytes were present. **Figure 13** illustrates the cells, which were assigned a rate of 0.0083 feet/day[2], with an extinction depth of 25 feet[3]. The model includes 153 cells, and this translates to maximum possible rate of 106.5 AF/yr (0.15 cfs).

5.5.4 Water Level Hydrographs

Because the overall volumes of pumpage are small, it has been assumed that the area of the model domain is in a steady-state condition, with groundwater levels in a long-term balance. **Figure 14** illustrates the locations for wells 55-645833 (near Harshaw Creek) and 55-809433 (along Sonoita Creek) near the Town. Hydrographs for these wells are presented in **Figure 15**. These wells appear to be fairly stable, with no significant changes over the period of record dating back to the late 1940s.

5.5.5 Regional Water Level Map

Because water levels appear to be in a steady state condition, the groundwater level map utilized available historic data, selecting the average value over the period of record. **Figure 5** illustrates the interpreted groundwater level contours and the available

[2] Based on ET rate developed by Nassereddin, 1967, p. 37

[3] If the groundwater level is above the extinction depth, evapotranspiration is computed; below that depth, evapotranspiration is ignored.

groundwater level data used to construct the contours. **Table 3** lists the groundwater levels used for the map. Ultimately, the groundwater level data were used for developing the starting groundwater levels (head distribution) for the model simulation.

5.5.6 Aquifer Properties

Nassereddin (1967) described various units of the alluvium that comprise the aquifer. The oldest and lowermost unit is a basal conglomerate that is less permeable than the overlying units due to cementation of the sediments. The cemented conglomerate is overlain by an unconsolidated sandy gravel, which according to Nassereddin (1967) is the most productive unit of the aquifer. Another productive unit is the Holocene alluvium along the flood plains of Sonoita Creek and its tributaries. This unit consists of sands, gravels and finer grained sediments. According to Nassereddin (1967), most wells in the basin are drilled into this unit. Nassereddin (1967) described two additional alluvial units, but stated that these are located above the water table.

Drillers' logs for the area are generally consistent with Nassereddin's descriptions. Many of the logs note the presence of a conglomerate, and some list the presence of "sandstone", which might indicate a higher degree of cementation.

Nassereddin (1967) reported an average transmissivity for the basin of 100,000 gallons per day per foot (gpd/ft) (13,367 ft^2/day). Transmissivity varies, with values calculated from aquifer tests ranging from 9,500 gpd/ft (1,270 ft^2/day) to 195,000 gpd/ft (26,066 ft^2/day) at two wells roughly one mile northeast of the Town. A specific yield value of 0.05 was reported for one of the tests. Transmissivity values calculated from specific capacity data ranged from 9,000 gpd/ft (1,200 ft^2/day) to 260,000 gpd/ft (34,755 ft^2/day).

Hydraulic conductivity is the transmissivity divided by aquifer thickness. An average transmissivity of 100,000 gpd/ft (13,367 ft^2/d) and an average aquifer thickness of 300 feet would indicate an average hydraulic conductivity of 45 ft/d for the entire basin. Values along Sonoita Creek are likely to be significantly higher than the average, due to the younger, less consolidated nature of the sediments in this area.

5.6 Surface Water Hydrology

A hydrologic model was built to determine the runoff hydrographs from Red Rock, Harshaw, and Sonoita Creeks for specific recurrence interval storms. Hydrographs are curves that show the flow rate and timing of runoff from a given storm. Recurrence interval storms are storms that have a specific likelihood of recurring each year, based on historical data. These storms are commonly called a 1-year storm, a 2-year storm, a 10-year storm, etc.; although that nomenclature is not perfectly accurate it is an intuitive way to describe storms. For example, a "2-year" storm is a storm that has a 50% chance of occurring in a given year. A "100-year storm" has a 1% chance of occurring in a given year; however, it is unlikely to occur only once every 100 years. In this study, three storms are modeled: 2-year, 10-year, and 50-year, 24-hour storm events. A 24-hour event means the storm's rainfall is assumed to occur over 24 hours.

A hydrologic model applies rainfall over an area and then calculates when and how much water will reach the discharge point of the watershed based on land use characteristics (is the watershed covered in forest or in pavement?), soil types (are the soils sandy and will infiltrate most of the rain, or are there primarily clays that will absorb very little rain?), land slopes, and other watershed characteristics. The output of the hydrologic model is a hydrograph that quantifies streamflow versus time at a particular location, and shows the rising and falling stream flowrate resulting from a storm event. The maximum flowrate in the stream resulting from the storm is known as the peak discharge. These runoff hydrographs become an input to the hydraulic model described later in this report.

Two readily available sources of peak discharge values exist that serve as the basis of the streamflow in this study- the values calculated by FEMA in 2011 and provided in the Flood Insurance Study (FIS), and StreamStats (a web-based USGS tool based on regression equations). These sources only provide peak discharges, they do not provide a full hydrograph. The flows calculated by the two programs are summarized in **Table 4**. The smallest storm modeled by FEMA was a 10-year storm. The smallest storm available from StreamStats is a 2-year storm.

Table 4 - Comparison of Peak Discharge

	FIS Peak Discharge (cfs)					StreamStats Peak Discharge (cfs)				
Location	**2yr**	**10 yr**	**50 yr**	**100 yr**	**500 yr**	**2yr**	**10 yr**	**50 yr**	**100 yr**	**500 yr**
Rock Creek	-	1,832	4,208	5,497	8,905	628	2,630	6,080	8,140	14,200
Harshaw Creek										
Below confluence with Red Rock	-	2,955	6,725	8,601	14,217	884	3,680	8,470	11,300	14,500
Above confluence with Red Rock	-	1,390	3,149	4,155	6,683	639	2,670	6,190	8,280	10,600
Sonoita Creek										
Below confluence with Harshaw	-	5,374	12,879	17,253	27,660	1,260	5,180	11,800	15,600	20,100
Above confluence with Harshaw	-	-	-	-	-	948	3,940	9,050	12,100	15,400

As illustrated in **Table 4**, StreamStats calculated peak discharges are higher than the calculated streamflow in the FIS along Harshaw, but lower along Sonoita Creek. For this study, peak discharge values from StreamStats were used for calibrating the hydrologic model, as StreamStats provides a flow estimate for a wider variety of storms. The Sonoita Creek streamflow numbers below the confluence with Harshaw are only provided for comparison between the FIS and StreamStats; these values are not used in the modeling. Flow in Harshaw is modeled as a separate creek until it joins Sonoita Creek; therefore, the Sonoita Creek streamflow was determined, in the model, upstream of the Harshaw confluence.

The watersheds analyzed in this report are shown in **Figure 16**. The Sonoita Creek watershed used in the model terminates upstream of the Town, just upstream of the confluence with Harshaw. The Red Rock Creek watershed encompasses the entire Red Rock Creek contributing area up to the location where Red Rock flows into Harshaw. The Harshaw Creek watershed includes contributing areas upstream of the Red Rock confluence.

As can be seen on **Figure 16**, the assumed watershed boundaries exclude some areas downstream of the Harshaw confluence with Sonoita and therefore do not capture all

areas which would contribute flow to Sonoita Creek within the Town. As noted above, the purpose of this model is to understand the change in streamflow and water surface elevation (stage) based on the addition of 10 cfs. All rainfall and snowmelt runoff that will enter Sonoita Creek within the Town will not be impacted by the increase in flow in Harshaw Creek. Therefore, even if this water were included in the model, it would be identical between the models, and it would not impact the comparison of "normal" storm event versus a "normal +10 cfs in Harshaw" storm event. The watersheds used were selected to represent the water that enters Sonoita up to the confluence of Harshaw to capture the flows impacted by the increase in streamflow in Harshaw Creek.

5.7 Hydrologic Modeling

As noted above, StreamStats provides a peak discharge but does not provide a complete hydrograph. Streamflow hydrographs are required for an unsteady-state hydraulic model (where flow in the creek changes over time). To generate hydrographs for these three watersheds, a simplified hydrologic model was constructed in Autodesk's Storm and Sanitary Analysis (SSA) software. SSA was used to perform calculations from United States Department of Agriculture Natural Resource Conservation Service (NRCS) TR-55's curve number method and Clark Unit Hydrograph. An SSA model was built for each watershed, and the model was used to generate hydrographs for each storm. The parameters required for these calculations are time of concentration (a fixed parameter based on watershed length and slope) and curve number (a parameter that represents watershed slope, land cover, soil type, etc.).

As discussed in the project kickoff meeting on January 12, 2020, a full hydrologic analysis was not included in the scope of this work, and the current modeling was based on flow estimates generated by others. This is in part because watershed characterization has already been completed by FEMA and the USGS to generate peak discharge values, therefore this work does not need to be duplicated.

The approach taken was to essentially reverse engineer the curve number method. The NRCS curve number method uses curve numbers to represent a variety of watershed parameters in an approach that is both quantitative and qualitative; quantitative in that a single curve number is selected, but qualitative in that the curve number represents a

variety of watershed parameters (soil type, land cover, land slope, antecedent moisture conditions, etc.). The curve number is not partitioned into the characteristics it is trying to represent, rather, a number is selected bearing all these parameters in mind. The curve number was iteratively changed in the SSA model until the calculated hydrograph had a peak discharge which approximated the peak discharge calculated by StreamStats (with a target of within 1%). This resulted in different curve numbers being used for different frequency storms for the same watershed.

In order to calculate the hydrograph, Clark Unit Hydrograph method was used in SSA. This method requires a watershed time of concentration. The time of concentration is physically based and was generated by measuring flow path length, slope, and other parameters in ArcGIS using the DEM discussed in Section 3.2.1. The time of concentration is based on the 2-hour, 24-hour storm intensity. This parameter helps determine the shape of the hydrograph.

Watershed characteristics used in the hydrologic model, including subbasin area, curve number, time of concentration, and peak discharge are summarized in **Table 5**. A hydrograph was generated for each 24-hour storm event and tributary:

- Sonoita Creek - 2-yr, 10-yr, and 50-yr storm
- Harshaw Creek - 2-yr, 10-yr, and 50-yr storm
- Red Rock Canyon - 2-yr, 10-yr, and 50-yr storm

The SSA calculated hydrographs were used as input to the hydraulic model as well as the groundwater model. After the runoff hydrographs were generated, a second set of hydrographs for Harshaw Creek were generated in Excel by adding a constant 10 cfs to the basin hydrographs.

Figures 17, 18, and 19 provides the hydrographs from each subbasin for the 2-year, 10, year, and 50-year frequency, 24-hour storms, respectively.

Table 5 - Watershed Information and Calculated Runoff

Watershed	Area (ft^2)	Curve Number			Time of Concentration	SSA Calculated Peak Discharge (cfs)		
		2-year	10-year	50-year		2-year	10-year	50-year
Harshaw Creek	20,950	66.29	69.37	83.25	4 hrs 20 min	639	2,671	6,191
Red Rock Creek	20,210	67.01	70.93	85.83	4 hrs 55 min	628	2,630	6,085
Sonoita Creek	47,760	63.78	65.26	77.24	5 hrs 2 min	949	3,941	9,053

ft^2 = Square feet
cfs = Cubic feet per second
NA = Not applicable

6.0 GROUNDWATER FLOW MODEL

Figure 20 illustrates the overall grid and boundary conditions used to simulate flow. The numerical groundwater flow model includes 573 rows and 355 columns of 100-foot square model cells, totaling 406,830 cells, with 205,754 active cells. The model has 2 layers, representing the alluvium and the underlying bedrock.

6.1 Model Structure

The top elevation of the groundwater model was established using DEM data from the USGS National Map (https://www.usgs.gov/core-science-systems/national-geospatial-program/national-map). These data are available as raster images at a 10-meter (3.28 feet) resolution. **Figure 21** shows the land surface elevation in the model area in feet above mean sea level (Meters-AMSL). These data were converted to feet above mean sea level for inclusion in the model.

6.1.1 Model Layers

The groundwater model was constructed using well data to establish the thickness of Layer 1, which represents the alluvial fill, as shown in **Figure 22**. Deep wells with drillers' logs were evaluated to estimate the thickness of alluvium, as noted on **Figure 22**. The Arizona Geological Survey (AZGS) has also compiled a map of the estimated depth to bedrock for alluvial basins (AZGS, 2007). The thickness of alluvium is contoured in purple on **Figure 22**. Generally, the alluvium varies from 0 to about 500 feet, which is consistent with the available data for the model area.

Layer 2 was added to accommodate recharge and underflow where the alluvium was not saturated. The layer is uniformly 394.4 feet thick in the model area.

6.1.2 Hydraulic Properties

Based on and evaluation of information from the Nassereddin (1967) thesis, the average hydraulic conductivity in the basin is approximately 45 ft/d with higher values near Sonoita Creek. Only one aquifer test was identified (Halpenny, 1964), conducted on a

well noted on **Figure 14**, which indicated transmissivity values of 101,000 to 212,000 gpd/ft (13,500 to 28,338 ft^2/day. Based on the available well information, this would represent a hydraulic conductivity of 259 to 544 ft/d. The test also indicated an estimated specific yield of 0.20.

Figure 23 shows the calibrated hydraulic conductivity for model Layer 1, which varies from 0.5 to 100 ft/d. The highest values parallel Sonoita Creek, and lower values are located in the upland areas. **Figure 24** shows the calibrated hydraulic conductivity for model Layer 2, which varies from 0.04 to 1.0 ft/d.

Storage parameters were uniformly set for the model domain, with confined specific storage set to 1.0 X 10^{-5} per ft (both layers) and specific yield set to 0.15 (Layer 1) and 0.03 (Layer 2). Although zones were established based upon the hydraulic conductivity zones, values remained constant as described for each layer.

6.1.3 Recharge

Groundwater underflow and mountain front / mountain block recharge were simulated using the recharge package, which was broken down by sub-watershed. The basic groundwater budget for the model domain includes recharge from precipitation, which exits the basin primarily as surface flow in Sonoita Creek south and west.

The PRISM (Parameter-elevation Regressions on Independent Slopes Model) Climate Group at Oregon State University collects and presents precipitation data for the United States (https://prism.oregonstate.edu/)**.** These data are converted to gridded data on an 800-meter grid spacing for the entire US[4]. Additional data products for average values are available for 2-kilometer grid spacing. These data are an excellent basis for estimating recharge rates.

Annual effective recharge rates have been calculated for the period 2000 to 2013, and are available (https://www.sciencebase.gov/catalog/item/55d383a9e4b0518e35468e58),

[4] These data are available annually, but have a high cost. The PRISM Climate Group also provides 30-year average annual values for free, as raster data for the continental US.

which were derived from regression analysis of the PRISM data. This process is documented in Reitz, Meredith, Sanford, W.E., Senay, G.B., and Cazenas, Jeffrey, 2017, *Annual estimates of recharge, quick-flow runoff, and ET for the contiguous US using empirical regression equations, 2000-2013: U.S. Geological Survey data release, https://doi.org/10.5066/F7PN93P0*. These estimates can form the basis for estimating model recharge rates.

Figure 25 illustrates the effective recharge rates in meters per year for 2013, using the gridded dataset. Assuming each cell represents 173.34 acres (based on number of cells and area covered), the average recharge rate (2000-2013) for the model watershed area was 11,338 AF/yr (15.7 cfs), which is shown on **Table 6**[5]. This represents 5.2% of total precipitation, based on the average rate of precipitation and the area of the watershed. Because all of the watersheds do not enter the model domain, a second estimate was made of only the watersheds which would enter the model domain, which is 9,220 AF/yr (12.7 cfs). This rate was determined to be high based on other published materials, and this estimate may fail to reflect losses to evapotranspiration or runoff accurately. For this reason, the effective recharge rates were used as a basis for recharge distribution in the model, with total rates calibrated to 3,412.7 AF/yr (4.7 cfs). Recharge zones for the model were set to represent mountain front recharge and locations of underflow. Recharge rates were entered to the model in units of ft/d, and MODFLOW converts this to a volumetric rate based on the area of each cell. **Figure 26** illustrates the calibrated recharge rates for the model. Ultimately, the recharge rate was calibrated to 3,412 AF/yr (4.7 cfs), or 1.6% of the watershed of the active model domain, consistent with estimates made by the USGS and other researchers.

Constant head cells were added to the model to simulate outflow at the southwest end in Layer 2. The flow simulated was 129 AF/yr (0.18 cfs). Although recharge and underflow (combined total) are significantly less than the initial estimates, it is likely that the model does not simulate all of the flow that enters or leaves the area, as the model

[5] The effective recharge raster datasets were analyzed for 2000-2013 for the model watershed area and the analysis is presented in Table 6.

does not cover the bedrock flows in full. Because the model outflows are largely surface baseflow in Sonoita Creek, the inflow rates essentially have to match the surface outflow. The recharge that enters the model from the tributary canyons and streams may have unaccounted losses prior to entering the model domain, such as ET and cross-basin underflow.

6.1.4 Evapotranspiration

MODFLOW can also incorporate evapotranspiration (ET) by applying a withdrawal of water from the model using a rate in feet per day to a depth limit defined as the extinction depth below which no evapotranspiration is assumed to occur. **Figure 13** illustrates the cells where evapotranspiration was simulated, with an extinction depth of 25 feet. If groundwater is less than 25 feet below the land surface for the model cell, then MODFLOW calculates an outflow rate based on the 0.0083 ft/d calibrated rate. This rate resulted in 94.5 AF/yr (0.13 cfs) of ET, which is much less than the estimated mass balance amount of 1,300 AF/yr (1.8 cfs) (**Table 1**). Based on the small area of phreatophytes mapped by CropScape, the ET rate estimated initially, appears to be too high.

6.1.5 Well Pumping

The steady-state simulation represents pre-development conditions with average groundwater pumping. Because water levels are observed to be generally stable, it is assumed that the existing pumping rates are too low to have any significant regional impacts, as evident from the stable water level hydrographs (see **Figure 15**). Pumping rates are presented in **Table 2**, and the simulated wells are shown on **Figure 4**. Overall simulated pumping is 266.7 AF/yr (0.37 cfs).

6.1.6 Stream Flow Routing Package

Surface flows in Sonoita Creek and Harshaw Creek were simulated using the streamflow routing package (SFR) for MODFLOW. This package specifies the geometry of the stream channel (width and length in each model cell, along with the slope of the channel. **Figure 20** shows the cells simulated with the SFR package, and **Figure 27**

shows a zoomed view near the Town. Each segment is broken into individual cells (reaches) which are numbered sequentially downstream starting with 1. Each new segment starts over with 1, with simulated flows routed to the next cell downstream. The SFR package computes flow and stage height for each cell, by subtracting or adding flow to and from groundwater in each cell based on the hydraulic conditions. If the groundwater level is below the bottom of the channel, then water will leak out of the channel into groundwater, with surface flow decreased. If groundwater levels are above the level of the stream bottom, then groundwater will discharge to the stream, increasing surface flow. The stream channel is specified in the SFR package using a width, length and conductance term for each model cell. Length is calculated for the stream length in each model cell, while width is either estimated from available data (such as Google Earth), or specified in a cross section. Flow to and from groundwater is calculated based on the individual cell conductance and the elevation of groundwater relative to the channel bottom. The conductance term is computed by multiplying the wetted area of the stream cell by a value of hydraulic conductivity. For this model, all stream cells were assigned a hydraulic conductivity of 0.1 ft/day which resulted in a good calibration to observed water levels (see discussion in Section 6.2).

The SFR package acts as a surface flow accounting system, tracking flow and adding or subtracting flows to/from groundwater. Stage height in each reach may be calculated using one of three methods:

- A simple rectangular channel, using Manning's equation;
- Flow tables, which specify stage at listed flow rates; or,
- An eight-point cross section to approximate the channel geometry.

The cross sections were developed for the surface water model, and were subsequently simplified into eight points for use in the numerical groundwater flow model. An example cross section is shown in **Figure 28**, for stream segment 15. The blue dots represent the points from the surface water model, and the numbered points indicate the points chosen for the 8-point representation in the groundwater model. Segments 3-19 were simulated using 8-point sections, while Segments 1, 2 and 20 used a rectangular channel. The model then estimates the stage height based upon the flow

rates and cross-sectional area. **Appendix D** includes figures outlining the cross sections for segments 3-19.

The base model simulation also includes 40,000 gallons per day of effluent releases from the Town's Wastewater Treatment Plant. These flows are added to segment 18 as runoff, meaning they are added to each reach (model cell) of stream segment 18 along its length.

6.2 Steady-State Model Calibration

The groundwater levels presented in **Figure 5** were used as model targets for calibration. The model calibration was conducted manually, with recharge rates and hydraulic conductivity zones and values adjusted to improve the statistical match between simulated and observed conditions. **Table 7** presents the statistical summary of the model, where the calibrated scaled root mean square error (RMSE) is 3.4%. Standard industry practice requires that model calibration should achieve a scaled RMSE that does not exceed 10%, but a scaled RMSE of less than 5% was chosen as the target for this project.

Table 7 – Steady-State Model Calibration Statistics

Statistic	Value
Residual Mean (ft)	-1.95
Absolute Residual Mean (ft)	16.12
Residual Std. Deviation (ft)	19.27
Sum of Squares (ft^2)	24,385.01
RMS Error (ft)	19.37
Min. Residual (ft)	-38.69
Max. Residual (ft)	52.04
Number of Observations	65
Range in Observations (ft)	570.11
Scaled Residual Std. Deviation (ft)	0.0338
Scaled Absolute Residual Mean (ft)	0.0283
Scaled RMS Error	3.40%
Scaled Residual Mean (ft)	-0.0034

Figure 29 illustrates the match between the measured target values and the model simulated values. The match is excellent, with simulated groundwater levels in the middle elevations of the model area slightly low, and the large cluster of groundwater levels in the Town split between positive and negative residual error.

Figure 30 illustrates the comparison between the measured groundwater levels and model simulated groundwater levels. The match is generally good, with contours of simulated and observed groundwater level data approximately parallel with similar hydraulic gradients between the simulated and observed data. This is an important factor in evaluating model calibration, because groundwater flows perpendicular to the contours, at a velocity that is proportional to the hydraulic gradient. The consistency between the contours of simulated and measured data indicate that the model accurately predicts groundwater flow directions and velocity.

Since groundwater flows perpendicular to, which indicates that groundwater flow directions and velocity Note that there are a mix of positive (model simulates too low) and negative (model simulates too high) residual errors across the model domain indicating there is no significant geographic bias in the calibration. The residual mean error of -1.95 indicates the simulated groundwater levels are slightly high but overall, the model falls within acceptable standards.

6.3 Sensitivity Analysis

As part of the model evaluation, a sensitivity analysis was completed, adjusting the horizontal hydraulic conductivity (K_x and K_y), the vertical hydraulic conductivity (K_z) and the recharge rates. A sensitivity analysis adjusts the model parameters individually by fixed multipliers, assessing the impact of each change on the model calibration. Hydraulic conductivity values (K_x, K_y, and K_z) were adjusted by factors of 0.1, 0.5, 1.0, 5.0 and 10.0. Recharge rates were adjusted by factors of 0.5, 0.8, 1.0, 1.2 and 1.5, since recharge rates are more generally constrained than conductivity values. Groundwater Vistas™ software automatically conducts the simulations and presents a sum of squares residual for each simulation.

6.3.1 Model Sensitivity for K_x

Figure 31 presents the ten most sensitive hydraulic conductivity zones based on the sum of squares residuals. The Y-axis shows the sum of squares residual, normalizing to 1.0. The X-axis shows the multiplier used. Based on these results, the model is most sensitive to variations in zones 1, 2 and then 8. These zones follow the main channels of both Sonoita and Harshaw Creeks and also coincide with the location of most of the water level observations, hence they are more sensitive than surrounding zones. Because the majority of the flow is in Layer 1, the model is most sensitive to the parameters in this layer. **Figure 23 and 24** lists the model hydraulic conductivity zones for each layer for reference.

6.3.2 Model Sensitivity for K_z

Figure 32 presents the sensitivity of the vertical hydraulic conductivity zones based on the standard deviation of the results. Clearly, the model is very insensitive to vertical hydraulic conductivity values, as the sum of squares did not change significantly. Based on these results, the model is most sensitive to variations in zones 7 and 5. The zones match those presented in **Figures 23 and 24** and coincide with the edges of the model where recharge is added to the model resulting in local downward vertical flow. Based on the sum of squares values, the vertical K sensitivity is much less than the horizontal K sensitivity.

6.3.3 Model Sensitivity for Recharge Rates

Figure 33 presents the sensitivity for the 9 zones (**Figure 26**) for recharge rates (Zone 1 is set to zero for the areas not receiving recharge). Generally, the model is not significantly sensitive to recharge across zones, although the range of multipliers used for this analysis range from 0.5 to 1.5, less than those used for hydraulic conductivity. The model is most sensitive to lower rates of recharge in Zone 3, which represents recharge from Big Casa Blanca Canyon. The model is most sensitive to higher rates of recharge in Zone 8, which represents recharge from Red Rock Canyon. This zone is also the second most sensitive to lower rates. Generally, the sensitivity of the model in the other zones is limited. The recharge sensitivity results indicate that a slight improvement in calibration may be possible by raising recharge from Zone 3. However, this improvement would not alter the results and conclusions of the model, therefore, it was not attempted.

7.0 HYDRAULIC ANALYSIS

A hydraulic model is a mathematical model used to determine how water moves in a stream and floodplain. Hydraulic models are typically either a steady state model or an unsteady model. The term steady state means that a constant rate of flow (usually the peak discharge) is applied throughout various stream segments. The rate of flow in the stream does not vary over time as there is no time component to a steady state model, it's just a snapshot of a given discharge. However, a steady state model provides limited information regarding the connectivity of various stream reaches and does not simulate backwater effects well (e.g. where a bridge constricts the flow in a stream). An unsteady model varies the stream flow over time by routing input hydrographs. A hydrograph is applied at the beginning of the stream reach (and along the stream reach as needed), and the model calculates how that flow moves from cross section to cross section down through the rest of the stream segments in the model. Previous modeling efforts by FEMA included only a steady state analysis of the Study Area. An unsteady model was used for this effort to better represent stream hydraulics around the bridge and because the groundwater model requires a hydrograph for input.

The purpose of constructing a hydraulic model in this study was to evaluate the change in flood risks within the Town due to the maximum potential continuous discharge of 10 cfs to Harshaw Creek. The hydraulic model was developed in the US Army Corp of Engineer's Hydrologic Engineering Center's River Analysis System (HEC-RAS). HEC-RAS is a standard hydraulic modeling platform used to evaluate flows through streams. A HEC-RAS model will calculate the maximum water surface elevation (stage) for a given storm at each cross section. That water surface is then applied to the stream and the adjacent floodplain to determine the depth of water in the stream and, as needed, in the floodplain. The HEC-RAS model was used to simulate the 24-hour 2-year, 10-year, and 50-year storm events without the 10 cfs. Then, the input hydrograph for Harshaw Creek was adjusted to include the continuous 10 cfs and the model was re-run.

The model used in this study was adapted from the geometry of the model developed by FEMA, but required updates to construct a stable model for unsteady flow. This

facilitated simulation of the water levels in the creek throughout the duration of a storm (not just at the time of peak discharge). All stream reaches were connected with stormwater moving freely between the separate reaches.

For the purposes of this study, in the HEC-RAS model, no water is allowed to infiltrate into the stream or floodplain, all water is conveyed through the model. In reality, infiltration will occur through the stream bed, stream banks, and (when present) into the floodplain. The zero-infiltration assumption is a conservative assumption that provides a maximum calculated water surface elevation (stage) throughout the model. Additionally, the HEC-RAS model assumes no lateral inflow from groundwater (see the groundwater modeling section of this report for more discussion of this assumption).

7.1 Study Area for the Hydraulic Model

At its simplest, a HEC-RAS model consists of a series of cross sections along a channel flow-path. These cross sections are located such that sufficiently realistic definition is given to the channel. An example cross section from the model is shown on **Figure 34**.

For the most recent mapping effort by FEMA, the model area (Town) was broken up into several distinct model areas which included Sonoita Creek and several tributaries – the lower portion of Harshaw Creek, the lower portion of Red Rock Canyon, and "Tributary A" located downstream of the Highway 82 Bridge over Sonoita Creek. There were also two separate models for the Sonoita Creek floodplains near the Highway 82 bridge that allowed water to leave the stream flood plain (e.g. on the north side water flows over SR82 to the west side of the road), then return to the stream later (the water that flows over SR82 flows along SR82 and returns to Sonoita Creek after the bridge). However, a greater number of connected tributaries on a stream greatly increase unsteady flow model stability. Therefore, the lower portion of Harshaw Creek and Sonoita Creek (**Figure 34**) were directly modeled. While the WTP2 flow into Harshaw Creek occurs roughly 10 miles upstream from the confluence with Sonoita, the 10 cfs constant discharge is introduced into the hydraulic model at the upstream boundary of the simulated length of Harshaw Creek, approximately one mile from the confluence. This conservatively assumes that none of the 10 cfs infiltrates or evaporates before it reaches the boundary of the surface water model. The flow from Red Rock Canyon was added to

Harshaw Creek as a lateral inflow, so that water is still accounted for in this model. This model also added several cross sections to Sonoita Creek downstream from the previous model boundary to ensure that any effects of flow from the Patagonia Wastewater Treatment Plant were fully accounted for.

7.2 Hydraulic Model Inputs

7.2.1 Flow Hydrographs from the Hydrologic Model

Inflow hydrographs were used as the boundary conditions for the upstream boundaries of the model and to simulate tributary flows from Red Rock Canyon. Additionally, for the 10-year and 50-year, 24-hour storm simulations, water flowed out of Sonoita Creek upstream of the Highway 82 bridge and into the left and right overbanks. This flow was accounted for as leaving the main model and used as the inflow boundary conditions on two separate floodplain flow models that convey the water until it returns to the stream (similar to the FEMA model described in the previous paragraph). The downstream discharge from each floodplain model was brought back into the main model as a lateral inflow at the appropriate cross section.

7.2.2 Model Geometry

The DEM described in Section 2.2 was used to generate model geometry including flow paths and cross sections. In some cases, the cross-sectional geometry from the FEMA model was used, although an unsteady flow model generally requires more channel definition than a steady state flow model. Therefore, a substantial increase in the number of cross sections was required for model stability. New cross sections were drawn and their geometry was generated using the raster DEM.

HEC-RAS's default is to take all of the water at a cross section and evenly distribute it across the cross section. However, particularly in natural systems, it's common that part of the floodplain area is lower than the bank elevation of the stream (see the example cross section on **Figure 34**). Therefore, HEC-RAS would automatically spread the water within the stream banks and within the low-lying areas of the floodplain. In reality, the water level in the creek will need to rise above the bank elevation before it can flow into

the floodplain. Therefore, HEC-RAS has a tool to define a certain elevation (specific to each cross section) in the model that the water surface must reach before it can move beyond that point laterally. This tool is called a levee point. Levee points were used in HEC-RAS to allow water to remain in the channel in many cross sections where overbank elevations were lower than that of the main channel.

To calculate water movement in a channel, the channel roughness (represented by the parameter "Manning's n") must be determined. Typical values for Manning's n are provided in literature and capture various effects that impact how freely water flows across a surface. These effects include quantity and type of vegetation within the flow area, channel straightness, presence and depth of shoals and depressions, and the presence and size of rocks and boulders. In the FIS, FEMA described the field work and literature review used to determine Manning's n values in the channel for their modeling. Based on review of the FIS documentation of Manning's n selection, the current study used that same Manning's n of 0.035 within all channels in all reaches, consistent with the FEMA modeling. Likewise, this model used a Manning's n value of 0.05 for floodplain areas outside the channel, consistent with the FEMA model.

7.3 Hydraulic Model Results

As described above, the standard storm events were modeled in HEC-RAS first, which did not include the 10 cfs continuous flow in Harshaw. A maximum water surface extent was generated for each event. After those analyses were completed, each storm event was modeled where the hydrograph for Harshaw Creek included the constant 10 cfs. Again, maximum water surface extent was generated for each event. The impact of 10 cfs can be determined by comparing the extent and the elevation of the water surfaces from each storm with and without the 10 cfs. **Figures 35a through 40** show water surface extents and comparison of the water depths. **Figures 35a, 37a, and 39a** show the extent of flooding without the 10 cfs and **Figures 35b, 37b, and 39b** show the extent of flooding with the 10 cfs added. **Figures 36, 38, and 40** show the calculated difference in water surface elevation between storms with and without the 10 cfs. Positive calculated differences indicate an increase in water level as a result of the added flow.

Hydraulic analysis for Sonoita Creek indicated a change of less than 0.5 inch in flood depth within the extent of the model with the addition of WTP2 discharge to Harshaw Creek. In addition, there is essentially no change in the flooded area due to the addition of the 10 cfs to the flood flows simulated. **Table 8** summarizes the results of the surface water model.

Table 8 - Summary of surface water modeling results

Simulated storm frequency and duration	Peak discharge at Sonoita Creek Bridge (cfs)		Increase in Peak Discharge at Sonoita Creek Bridge (cfs)	Maximum increase in maximum flood surface depth across watershed (inches)	% Channel Water Height at Location of Maximum Increase
	Without 10 cfs in Harshaw Creek	With 10 cfs in Harshaw Creek			
2-year, 24-hour	2,176	2,186	10	0.39	0.7%
10-year, 24-hour	8,891	8,902	11	0.27	0.2%
50-year, 24-hour	12,346	12,347	1	0.35	0.2%

7.4 Sensitivity Analysis for Hydraulic Model

A sensitivity analysis was conducted for this study to determine the impact to model results of small changes to an assumed parameter. The primary parameter which is assumed for the hydraulic model is Manning's roughness coefficient, n. As described above, a Manning's n of 0.035 was assigned to the channels in all reaches of the model to match the n selected by FEMA. The sensitivity analysis was only conducted for unsteady flow which included the additional 10 cfs into Harshaw Creek from WTP2.

The Manning's n was modified across the model either by increasing or decreasing n in the channel to assess how sensitive the model was to changes in assumed roughness. For the 2-year, 24-hour storm simulation, changes in channel roughness minimally affected peak discharge at various locations throughout the model. At the locations where comparisons of peak discharge were made, the largest change in peak discharge

was -0.56% when n was changed from 0.035 to 0.05. It should be noted that a change in channel n from 0.035 to 0.05 is a large shift in assumed roughness.

The effect of changing Manning's n on peak discharge throughout the model was more notable in the 10-year and 50-year, 24-hour storm simulations. This effect was most evident where water backs up near the bridge and is shown to cross over Highway 82. To illustrate the impact of the change in Manning n, **Table 3** shows the peak flow over Highway 82 in the left and right overbank near the bridge for various Manning's n. **Table 4** summarizes the difference between the peak discharges in **Table 9** when n is adjusted away from n=0.035 (the value used in this study).

Tables 9 and 10 illustrate that the model is sensitive to the assumed Manning's n in the channel. As would be expected, if Manning's n is lowered, roughness is decreased and water moves through the channel more quickly and there is less flooding. If Manning's n is raised, roughness is increased and water is slowed resulting in more water going over Highway 82.

Table 9 - Peak flow overtopping Highway 82 near Sonoita Cr. Bridge for varying channel roughness (n)

		Peak discharge: 10-yr, 24-hour (cfs)				Peak discharge: 50-yr, 24-hour (cfs)

8.0 GROUNDWATER MODEL SIMULATIONS

As outlined in Section 4.1, the groundwater flow model was used to evaluate the impacts from the discharges from the WTP2 at the Hermosa Mine into Harshaw Creek. The proposed discharge of 10 cfs will be added to Harshaw Creek at the location noted on **Figure 1.** The model-simulated discharge point was established at a location approximately 10 miles downstream from the actual proposed WTP2 discharge location thereby conservatively assuming that all of the 10 cfs discharge flows to Sonoita Valley with no losses from infiltration or evapotranspiration. Simulations including 10 cfs of flow in Harshaw Creek are added to the streamflow routing package (SFR) at the edge of the model domain where Harshaw Creek enters the domain.

Simulations were also conducted to evaluate the impact of flood events on groundwater levels, based upon the surface water model results. The purpose of these simulations was to determine whether the additional flooding or high groundwater levels may be expected in conjunction with the WTP2 discharges.

8.1 Impact of Harshaw Creek Discharge

A groundwater simulation was completed which included 10 cfs of surface flow added to Harshaw Creek for a 5-year period, followed by 5 years of recovery with no flow. **Figure 41** illustrates the change in groundwater levels after 5 years of continuous flow in Harshaw Creek. The largest increase occurs along Harshaw Creek near the start of the first segment. Water levels rise between 2 to 3 feet in the area of the Town, increasing to the east and south.

Figure 42 shows the change in groundwater levels after 5 years of flow, then 5 years of recovery with no flows. Residual groundwater level rises exceed 1 foot in few areas, but have recovered to within a foot in most areas.

Figure 41 also shows the minimum depth to water levels measured at wells historically. The shallowest measurement was 7 feet, at well 55-809433. The change simulated at this location is 2.30 feet after 5 years, and **Figure 43** illustrates the impact of 2.30 feet of

additional rise compared to measured depth to water historically. As evident, 2.30 feet of water level rise would not result in water reaching land surface.

Figure 44 illustrates the flow in Sonoita Creek after 5 years of undiminished inflow, after 10 years (5 years of recovery) and the simulated steady-state flow. This profile shows the simulated flow rate down the channel from the northeastern end of the model. Flow from Harshaw Creek joins Sonoita Creek at about 45,000 feet down the channel, and rises as baseflows are added beyond the Town. Based on these simulation results, baseflow conditions prior to the releases will return within 5 years after flows cease.

8.2 Harshaw Flows with 2-Year Storm Event

A simulation was conducted which included a 2-year recurrence interval storm event added onto the end of the 5-year flow in Harshaw Creek, to determine whether the impact of storm events would be greater with flows in Harshaw Creek. The event covers a 48-hour period, which is the time for which a precipitation event gathers and enters the streams. The model simulates 5 years of flow using annual stress periods, and then includes 48 hours of 10-minute stress periods. Flow data for the storm event were derived from the surface water model simulations. **Figure 45** illustrates flow at the State Route 82 bridge[6]. These flow rates are similar to the flows simulated in the surface water model. Maximum flow is 2,169 cfs after 16 hours at the bridge.

Figure 46 shows the additional change in groundwater levels due to the 2-Year recurrence flood event, after 5 years of 10 cfs flow in Harshaw Creek. The difference map represents the change after 48 hours of the flow event. The additional water level rises are less than 0.5 feet, and are generally 0.1 to 0.3 feet. These changes are confined to the areas immediately adjacent to Harshaw and Sonoita Creeks. Based on these data, groundwater levels will rise less than half a foot from a 2-year recurrence storm event during the Harshaw Creek 10 cfs discharge period.

[6] This figure also includes the flows from a 50-Year recurrence flood event which will be discussed in the next section.

Figure 47 illustrates changes in simulated groundwater levels at well 55-809433 during the flood events. This well has the shallowest measured depth to water (7 feet), and the model is simulating an additional 0.2 feet of rise during the 2-Year recurrence storm event. This additional rise in water levels would not reach land surface.

8.3 Harshaw Flows with 50-Year Storm Event

As noted, a second simulation was conducted based on the 50-year recurrence flood event. As noted in **Figure 45**, the flows are much greater, with a peak discharge of 21,061 cfs after over 15 hours. A 50-year flood event will cause significant flooding in the Town, and will cause groundwater level rises. **Figure 47** also shows the increase in water levels at well 55-809433 during the 50-Year flood event. The change is approximately 0.6 feet, peaking after 24 hours of flow.

Figure 48 shows the change in groundwater levels after 24 hours of flood flows, as this approximately represents the greatest change. Some areas have over 2 feet of groundwater level rise, particularly along Harshaw Creek. Since the depth to water in this area exceeds 30 feet historically, this change will not result in groundwater reaching land surface.

9.0 CONCLUSIONS

Groundwater and surface water modeling were used to assess the potential impact of discharging 10 cfs of treated water from the AMI Hermosa Project into Harshaw Creek. The Town was concerned that the additional flow to Harshaw Creek would increase groundwater levels through recharge along Harshaw and Sonoita Creeks as well as exacerbate flood flows in the town. The modeling performed as part of the project was designed to quantify impacts using industry-accepted techniques, assumptions, and software.

The result of the modeling indicates that a constant inflow of 10 cfs to Harshaw Creek from WTP2 (assuming no infiltration or evapotranspiration losses for approximately 9 miles of flow) would have minimal impacts to flood flows in the Town during the simulated 2-year, 10-year, and 50-year, 24-hour storm events. Projected surface water level rises attributable to the 10 cfs are less than 0.5 inch. As can been seen in **Table 4**, 10 cfs is a very small percentage of even the 2-year storm event, therefore, the impact to stormwater water surface elevation is small.

The groundwater modeling shows that the addition of 10 cfs to Harshaw Creek would cause groundwater mounding along both Harshaw and Sonoita Creeks with the maximum predicted mounding to be about 4.5 feet after 5 years of flow. The area of projected maximum water level rise is where Harshaw Creek enters the basin. Within the Town, projected water level rises are mostly in the range of 2 to 3 feet. After five years of recovery, groundwater levels were predicted to return to pre-discharge levels. Additional mounding from flood events on top of the long-term discharge impacts was also evaluated. For the largest flood event, the 50-year, 24-hour event, additional mounding of up to two feet may occur. Under no scenarios simulated did groundwater mound to ground surface except in the areas of predicted perennial flow along Sonoita Creek where it already is at the ground surface.
